

Pseudo-code for the Markov random field clustering algorithm

The idea of the algorithm

The aim of the clustering is to segment the dynamic PET image automatically, which then enables an automatic extraction of the reference tissue input function. The segmentation algorithm presented in the article of Chen et al. [Chen et al. 2001] uses a Markov random field model for the TAC class labels because this enables to incorporate spatial interaction between voxels in the segmentation process. The algorithm used in the segmentation is the Expectation Maximization (EM) algorithm.

The algorithm proceeds in principle in the same way as the algorithm of Ashburner et al., which is introduced in the Appendix A. The main difference is that in the method of Ashburner et al. it is assumed that image voxels are independent while the Markov random field model enables us to take into account the correlation of voxels close to each other. There are also some differences in the ways of computing cluster means and variances. TAC i is denoted a_i and its component in time frame j is denoted a_{ij} . Cluster label for TAC i is denoted z_i and it is assumed that the number of clusters is k . The algorithm proceeds as follows.

1. Define a neighbourhood for each voxel in the original data matrix and then create a matrix having voxels as rows and time frames as columns. The neighbourhood of a voxel is defined to be a 3×3 voxel grid.
2. Set initial belonging probabilities for each TAC and define the initial clusters. The initial belonging probabilities are set to be either zero or one.
3. Compute means and variances for each cluster.
4. Compute probability densities for each TAC given a cluster, i.e. probability densities $p(a_i | z_i = k)$. These probabilities are based on the Gaussian distributions.
5. Compute probabilities for each class label z_i given the neighbourhood N_i of voxel i . The Markov random field model is used in calculating these probabilities.
6. Calculate new belonging probabilities and define new clusters by assigning each TAC to a cluster such that the belonging probabilities are maximized.
7. Compute the value of log likelihood and if it has increased significantly since the previous iteration, continue iterating from step two.

Pseudo-code

```
/* Define the neighbourhood of each element in the original data matrix. It is assumed that there are  
X rows and Y columns in the original data matrix. The neighbourhood is selected to be a 3x3  
voxel grid.
```

```
The set  $N_{(x,y,plane)}$  contains the neighbours of voxel in place  $(x,y,plane)$  in the data matrix. */
```

```
for each plane
```

```
  for x = 1 to X
```

```
    for y = 1 to Y
```

```
       $N_{(x,y,plane)} = \{ (x-1,y-1), (x-1,y), (x-1,y+1), (x,y-1), (x,y+1),$   
         $(x+1,y-1), (x+1,y), (x+1,y+1) \}$ 
```

```

endfor
endfor
endfor

```

/* It is assumed that matrix A has voxels as rows and time frames as columns and that the variable N_i includes the neighbourhood of a voxel that is on the i :th row in the matrix A .

It is also assumed that there are m rows (voxels) and n columns (time frames) in the matrix A and an element of A in place (i,j) is denoted a_{ij} . From now on, the input of the algorithm is the matrix A . */
